Programming in Python

GAVRILUT DRAGOS

COURSE 4

All exceptions in python are derived from **BaseException** class. There are multiple types of exceptions including: **ArithmeticError**, **BufferError**, **AttributeError**, **FloatingPointError**, **IndexError**, **KeyboardInterrupt**, **NotImplementedError**, **OverflowError**, **IndentationError**, and many more.

A list of all the exceptions can be found on:

- https://docs.python.org/3.5/library/exceptions.html#Exception
- https://docs.python.org/2.7/library/exceptions.html#Exception

A custom (user-defined) exception type can also created (more on this topic at "Classes").

Exceptions in Python have the following form:

```
Python 2.x / 3.x
                                        Python 2.x / 3.x
                                        def Test (y):
try:
   #code
                                            try:
                                                 x = 5 / y
except ExceptionType1:
   #code for exception of type 1
                                            except ArithmeticError:
                                                 print("ArithmeticError")
except ExceptionType2:
   #code for exception of type 1
                                            except:
                                                 print("Generic exception")
except:
                                            else:
   #code for general exception
else:
                                                 print("All ok")
                                                                     Output
   #code that will be executed if
                                                                     ArithmeticError
   #there is no exception
                                        Test(0)
                                                                     Generic exception
                                        Test ("aaa")
                                                                     All ok
                                        Test(1)
```

Python also have a finally keyword that can be use to executed something at the end of the try block.

```
Python 2.x / 3.x
                                       Python 2.x / 3.x
                                       def Test (y):
try:
                                                                      Output
   #code
                                            try:
                                                x = 5 / y
except:
                                                                      Test(0):
   #code for general exception
                                            except:
                                                                        Error
else:
                                                print("Error")
                                                                       Final
   #code that will be executed
                                            else:
                                                print("All ok")
   #if there is no exception
                                                                      Test(1):
finally:
                                            finally:
                                                                       All ok
   #code that will be executed
                                                print("Final")
                                                                        Final
   #after the try block execution
                                       Test(0)
   #is completed
                                       Test(1)
```

Exceptions in Python have the following form:

```
Python 2.x / 3.x
                                       Python 2.x / 3.x
                                       def Test (y):
try:
   #code
                                           try:
except (Type<sub>1</sub>, Type<sub>2</sub>, ...Type<sub>n</sub>):
                                                x = 5 / y
   #code for exception of type
                                           except (ArithmeticError, TypeError):
   #1,2,...
                                                print("ArithmeticError")
except:
                                           except:
   #code for general exception
                                                print("Generic exception")
else:
                                           else:
   #code that will be executed
                                                print("All ok")
                                                                            Output
   #if there is no exception
                                                                            ArithmeticError
                                       Test(0)
                                                                            ArithmeticFrror
                                       Test ("aaa")
                                                                            All ok
                                       Test(1)
```

Python has a special keyword (assert) that can be used to raise an exception based on the evaluation of a condition:

```
Python 2.x / 3.x

age = -1
try:
    assert (age>0), "Age should be a positive number"
except Exception as e:
    print (e)
```

Output

Age should be a positive number

Modules

Python distribution modules:

- Python 3.x → https://docs.python.org/3/py-modindex.html
- Python 2.x → https://docs.python.org/2/py-modindex.html

Module	Purpose
collections	Implementation of different containers
ctype	Packing and unpacking bytes into c-like structures
datetime	Date and Time operators
email	Support for working with emails
hashlib	Implementation of different hashes (MD5, SHA,)
json	JSON encoder and decoder
math	Mathematical functions
OS	Different functions OS specific (make dir, delete files, rename files, paths,)

Module	Purpose
re	Regular expression implementation
random	Random numbers
socket	Low-level network interface
subprocess	Processes
sys	System specific functions (stdin,stdout, arguments, loaded modules,)
traceback	Exception traceback
urllib	Handling URLs / URL requests, etc
xml	XML file parser

Modules - sys

Python documentation page:

- Python 3.x → https://docs.python.org/3/library/sys.html#sys.modules
- Python 2.x → https://docs.python.org/2/library/sys.html#sys.modules

object	Purpose
sys.argv	A list of all parameters send to the python script
sys.platform	Current platform (Windows / Linux / MAC OSX)
sys.stdin sys.stdout, sys.stderrr	Handlers for default I/O operations
sys.path	A list of strings that represent paths from where module will be loaded
sys.modules	A dictionary of modules that have been loaded

Modules - sys

```
Python 2.x/3.x (File: sum.py)

import sys
suma = 0

try:
    for val in sys.argv[1:]:
        suma += int(val)
    print("Sum=", suma)

except:
    print("Invalid parameters")
```

Output

```
>>> python.exe C:\sum.py 1 2 3 4
Sum = 10
>>> python.exe C:\sum.py 1 2 3 test
Invalid parameters
```

Python documentation page:

- Python 3.x → https://docs.python.org/3/library/os.html
- Python 2.x → https://docs.python.org/2/library/os.html

Includes functions for:

- Environment
- Processes (PID, Groups, etc)
- o File system (change dir, enumerate files, delete files or directories, etc)
- File descriptor functions
- Terminal informations
- Process management (spawn processes, fork, etc)
- Working with file paths

Listing the contents of a folder (os.listdir \rightarrow returns a list of child files and folders).

Python 2.x/3.x

```
import os
print (os.listdir("."))
```

Output

['\$Recycle.Bin', 'Android', 'Documents and Settings', 'Drivers', 'hiberfil.sys', 'Program Files', 'Program Files (x86)', 'ProgramData', 'Python27', 'Python35', 'System Volume Information', 'Users', 'Windows', ...]

File and folder operations:

- os.mkdir / os.mkdirs → to create folders
- os.chdir → to change current path
- os.rmdir / os.removedirs → to delete a folder
- os.remove / os.unlink → to delete a file
- os.rename / os.renames → rename/move operations

os has a submodule (**path**) that can be use to perform different operations with file/directories paths.

Python 2.x/3.x

```
import os
                                                       Output
print (os.path.join ("C:","Windows","System32"))
print (os.path.dirname ("C:\\Windows\\abc.txt"))
print (os.path.basename ("C:\\Windows\\abc.txt"))
                                                       abc.txt
print (os.path.splitext ("C:\\Windows\\abc.txt"))
print (os.path.exists ("C:\\Windows\\abc.txt"))
                                                       False
print (os.path.exists ("C:\\Windows\\abc.txt"))
                                                       True
                                                       False
print (os.path.isdir ("C:\\Windows"))
                                                       False
print (os.path.isfile ("C:\\Windows"))
print (os.path.isfile ("C:\\Windows\\abc.txt"))
```

C:\Windows\System32
C:\Windows
abc.txt
["C:\Windows\abc", ".txt"]

Listing the contents of a folder recursively.

```
Python 2.x/3.x
import os
for (root, directories, files) in os.walk("."):
       for fileName in files:
              full fileName = os.path.join(root, fileName)
              print (full fileName)
```

os module can also be used to execute a system command or run an application via system function

```
Python 2.x/3.x
import os
os. system("dir *.* /a")
```

Output

.\a

```
.\a.py
.\all.csv
.\run.bat
.\Folder1\version.1.6.0.0.txt
.\Folder1\version.1.6.0.1.txt
.\Folder1\Folder2\version.1.5.0.8.txt
```

Input/Output

Python has 3 implicit ways to work with I/O:

- A) IN: via keyboard (with **input** or **raw_input** keywords)
- There are several differences between python 2.x and python 3.x regarding reading from stdin
- B) OUT: via print keyword
- C) IN/OUT: via **open** keyword (to access files)

Input/Output

input keyword performs differently in Python 2.x and Python 3.x:

- o In Python 2.x, the content read from the input is evaluated and returned
- o In Python 3.x, the content read from the input is considered to be a string and returned

Format (Python 2.x/3.x)

input ()
input (message)

Python 2.x / 3.x

x = input("Enter: ")
print (x, type(x))

 Use raw_input in Python 2.x to obtain the same effect as in Python 3.x

Python 2.x	Python 3.x
>>> Enter: 10	>>> Enter: 10
(10, <type 'int'="">)</type>	10 <class 'str'=""></class>
>>> Enter: 1+2*3.0	>>> Enter: 1+2*3.0
(7.0, <type 'float'="">)</type>	1+2*3.0 <class 'str'=""></class>
>>> Enter: "123"	>>> Enter: "123"
('123', <type 'str'="">)</type>	"123" <class 'str'=""></class>
>>> Enter: test !!!ERROR!!! (test can not be evaluated)	>>> Enter: test test <class 'str'=""></class>

Input/Output

print can be used to print a string in both Python 2 and Python 3. In Python 3 print is a function and supports multiple parameters:

```
Format (Python 3.x)
print (*objects, sep='', end='\n', file=sys.stdout, flush=False)
```

A file can be open in python using the keywork open.

Format (Python 3.x)

```
FileObject = open (filePath, mode='r', buffering=-1, encoding=None, errors=None, newline=None, closefd=True, opener=None)
```

Format (Python 2.x)

```
FileObject = open (filePath, mode='r', buffering=-1)
```

Where mode is a combination of the following:

```
"r" - read (default)
"w" - write
"x" - exclusive creation (fail if file exists)
"a" - append
"b" - binary mode
"t" - text mode
"+" - update (read and write)
```

Python 3 also supports some extra parameters such as:

- o encoding → if the file is open in text mode and you need translation from different encodings (UTF, etc)
- \circ error \rightarrow specify the way conversion errors for different encodings should be processed
- newline → also for text mode, specifies what should be consider a new line. If this value is set to None the character that is specific for the current operating system will be used

Documentation for open function:

- Python 3.x → https://docs.python.org/3/library/functions.html#open
- Python 2.x → https://docs.python.org/2/library/functions.html#open

A file object has the following methods:

- f.close → closes current file
- o f.tell → returns the current file position
- f.seek → sets the current file position
- f.read → reads a number of bytes from the file
- \circ f.write \rightarrow write a number of bytes into the file
- o f.readline → reads a line from the file

Also – the file object is iterable and returns all text lines from a file.

```
Python 2.x/3.x

for line in open("a.py"):
    print (line.strip())
```

Lines read using this method contain the line-feed terminator. To remove it use strip or rstrip.

Functional programming can also be used:

```
Python 2.x/3.x x = [line for line in open("file.txt") if "Gen" in line.strip()] print (len(x))
```

To read the entire content of the file in a buffer:

```
Python 2.x/3.x

data = open("file.txt", "rb").read()
print (len(data))
print (data[0])
```

read method returns a string in Python 2.x and a buffer in Python 3.x \rightarrow The output of the previous code will be a character (in Python 2.x) and a number representing the ascii code of that character in Python 3.x

To obtain a string in Python 3.x use "rt" instead of "rb"

To create a file and write content in it:

```
Python 2.x/3.x

open("file.txt", "wt").write("A new file ...")
```

It is a good policy to embed file operation in a try block

```
try:
    f = open("abc.txt")
    for line in f:
        print(line.strip())
    f.close()
except:
    print("Unable to open file abc.txt")
```

Once a file is open, the file object handle can be use to retrieve different information regarding that file:

```
Python 2.x/3.x

f = open("a.py","rb")
print ("File name : ", f.name)
print ("File open mode : ", f.mode)
print ("Is it closed ? : ", f.closed)
```
